Abstract

In this study, we fabricated PCL-nanoparticles by encapsulating dual drugs as amphotericin B and doxorubicin via double-emulsion solvent evaporation method also incorporated with ligand-lectin for targeting the infested macrophage cells and prove importance against VL. Different independent processing parameters were assessed systematically to enhance the incorporation of the dual agents with different properties (AmB and DOX, hydrophobic & hydrophilic molecule, respectively) into PCL-NPs and control particle size. Approaches investigated for the enhancement of drug entrapment efficiencies and smaller particle size included the influence of the drug content, polymer content, sonication time etc. The mean particle size and zeta potential of PCL-NPs were 236.7 ± 0.04 nm in diameter and -9.11 ± 3.46 mV, respectively. The entrapment efficiencies of AmB and DOX were 82.1 ± 1.39 and 75.20 ± 0.14 %, respectively. Antileishmanial activities of the formulations and various combination approaches were assessed using macrophage-specific ligand-lectin. The prepared plain and lectin coated PCL-NPs based systems showed remarkable potential for passive and active intra macrophage targeting, respectively and the approach could be a successful alternative to the currently available drug regimens against VL. Multidrug resistance can be improved by combination delivery of encapsulated anti VL drugs. Thus, the co-encapsulation of AmB and DOX should reduce side effects of both drugs while increasing efficacy.

Keywords: PCL-Nanoparticles, amphotericin B, doxorubicin, lectin, macrophages, macrophage targeting

Pharm Biomed Res 2017; 3(1): 14-21

Introduction

Visceral leishmaniasis (VL) also known as kala-azar caused by “*Leishmania donovani*” and transmitted by the sandfly, “*Phlebotomus argentipes*” is the most severe form of leishmaniasis and is almost fatal, if left untreated. It results from infection of the macrophages of the liver, spleen and bone marrow. The symptoms of conventional disease are fever, weight loss, hepatosplenomegaly and pancytopenia. It occurs in more than 80 countries in Africa, Asia, Southern Europe and South America. Approximately 500,000 new cases of VL occur worldwide each year. India alone may contribute as much as 40-50% of these with 90% occur in the state of Bihar (1).

Despite the accessibility of several drugs, currently existing therapies for VL are very toxic and also started showing emergence of drug-resistant parasitic strains. For instance, pentavalent antimonials (sodium stibogluconate) and pentamidine were potent drugs used against VL; but there is emerging evidence that the rates of response are declining due to the appearance of resistance, relapses due to the emergence of several unresponsive strains of the leishmanial parasite and toxicity (hypotension, reversible hypoglycemia, and

nephrotoxicity) (2). Miltefosine is a relatively new anti-VL drug which holds significant potential in treating VL along with other first-line therapeutics (3); however, primary mechanism is quite uncertain, and possible impairment of lipid metabolism occurs. Despite all research initiatives and pre-clinical studies, effective therapy for VL still remains challenge holding direct negative implications with respect to better drug targeting and overcoming drug resistance (3). Amphotericin B (AmB) is used as a prototype leishmanicidal drug due to its excellent efficacy and its use results in fewer treatment failures and relapses (4, 5). However, the important side effects, mainly nephrotoxicity, produced by this drug at therapeutic doses have often led to its rejection as a first-choice treatment. Counter intuitively, doxorubicin (DOX), an anthracycline antibiotic widely used anticancer agents (6), was reported to be equally effective (in comparison to amphotericin) as an anti-VL agent based on the studies conducted by Sett *et al.* and other researchers (7). Although highly potent, activity of DOX has been restricted by its fatal toxicity, cost-effectiveness, dose limited cardiotoxicity and myelosuppression (8, 9). The problem requires that the drug should be targeted to the macrophages in such a way that the interaction of the free drug

with non-target tissues could be minimized (10). The possibility of improving the plasma half-life of the drug-polymer conjugate, with maximum accumulation in the target site, can be achieved through encapsulation of the drug in a long circulating carrier such as liposomes or nanoparticles. Out of these carriers, the biodegradable Nano-particulate systems (NPs) have recently received considerable attention as potential drug delivery systems (11).

The aim of the present work is to formulate poly- ϵ -caprolactone-nanoparticles (PCL-NPs) with a view towards vectoring combination of drugs (AmB and DOX) to RES incorporated with macrophage targeted ligand- lectin and generated an excellent tool that can circumvent major drug related issues in the treatment of VL. One such approach to increase the efficacy and to reduce the dose related toxicity of these drugs is to target the drug molecule to the phagolysosomes of the MPS where the leishmania parasites reside (12). These nanoparticles are suitable for passive and active targeting of drugs to MPS and can result in higher concentrations of drug in liver and spleen on parenteral administration (9). They can be passively taken up from the blood stream by the macrophages of the liver and spleen after intravenous or intracardiac administration because of their colloidal nature. The PCL-NPs are stable formulations that could be an economically attractive substitute of the already licensed AmB and DOX formulations. Concurrently, ligand mediated active targeting to the macrophages with the proposed PCL-NPs would considerably increase the rate and extent of macrophage accretion of drug which may further decrease the dose size and dose frequency of already approved formulations.

Materials and methods

Materials

Amphotericin B (AmB) was procured as a gift sample from Lifecare Innovations, Gurugram, India. Doxorubicin Hydrochloride (DOX) was received as gift sample from Sun Pharmaceuticals Industries Limited, India. Poly- ϵ -caprolactone (PCL) (85,000 Da), lectin (WGA), poly-vinyl alcohol (PVA, Av. MW 30,000-70,000), Eagle's medium and Locke's solution (MWCO: 3500) were purchased from Sigma Chemical Co. USA. All other chemicals used were of analytical reagent grade and without further purification.

Preparation of PCL-nanoparticles

PCL-nanoparticles (PCL-NPs) containing AmB and DOX were prepared by using double emulsion method with slight modification as per our laboratory set up (13). In a small plastic vial 58.9 mg PCL was mixed with 1 ml of chloroform and

added in previously extracted DOX under magnetic stirring (Remi, Mumbai, India). After which DOX solution was added in 0.1% w/v PVA solution. In a separate plastic vial 0.5 mg AmB was dissolved in 0.2 mL dimethyl sulphoxide (DMSO) and injected into PVA solution and resulted emulsion was stirred at room temperature under probe sonicator (Sonics, Vibracell) at 10,000 rpm, for 15 min. The resultant PCL-NPs were separated by ultracentrifugation at 16,000 rpm (Sigma 3K- 18 refrigerated centrifuge, Germany) for 30 min and washed with distilled water at least three times (14).

Optimization of PCL-nanoparticles

Optimization of PCL-Nanoparticles was carried out by varying different parameters such as drug content, polymer content and sonication time. For optimization of drug content (AmB and DOX) to polymer content, polymer content (50 mg) and sonication time (5 min) were kept constant while AmB and DOX content was varied at different weight levels, i.e. (2, 3, 4, 5 mg for AmB and 5, 10, 15, and 20 mg for DOX) in different formulations (Table 1) for determining optimum AmB and DOX content (15). Average particle size of different formulations was determined by particle size analyzer (Delsa Nano C, Beckman Coulter, USA) and percent drug entrapment in different formulations was also determined as described previously (16). PCL-NPs with optimum AmB and DOX to polymer content were optimized for optimum sonication time in terms of average particle size. PCL content, drug content (AmB and DOX) to polymer content (optimized), and % w/v PVA concentration were kept constant while sonication time was varied (i.e. 5, 10, 12, 15, 20 min) for different formulations. PCL-NPs were evaluated for average particle size by photon correlation spectroscopy using Zetasizer Nanoseries (Nano-ZS, Malvern Inst. Ltd. UK) using a flow-through cell and percent drug entrapment in different formulations was also determined. We have found maximum drug encapsulation efficiencies with optimum sonication time at 15 min. Formulation with optimum drug content and sonication time were optimized for optimum polymer content (PCL) in terms of percent drug entrapment. The PCL-NPs with fixed drug content, sonication time with different polymer content (PCL) (i.e 50, 100, 150, 200 mg) were prepared (12). Drug content and sonication time however were kept constant at its optimum level. Increasing the amount of PCL from 50-200 mg caused NPs size shift toward a higher size range from 236.7 to 572 nm, and entrapment efficacy of AmB and DOX was decreased from to 82.1 ± 1.39 to 55.76% and 75.20 ± 0.14 to 32% respectively (10). PCL-NPs were evaluated for percent drug entrapment and percent haemolysis. Percent haemolysis was determined by the method reported in

literature (16). The optimization method for PCL-NPs was done to produce NPs of small size with high entrapment efficiency (Figure 1).

Figure 1 Optimization of sonication time in terms of average particle size total polymer used (PCL) - 50 mg, AmB- 5 mg, DOX- 10 mg

To incorporate the surface of PCL-NPs with lectin, a modified emulsion-solvent evaporation method ($w_1/o/w_2$) was performed with slight modification as per our laboratory setup (17). For coating, 1 mL PCL-NPs was incubated and gently stirred with 3 mL lectin dispersion at room temperature. The hardened PCL-NPs were washed twice with distilled water by ultracentrifugation (Sigma 3K-18 refrigerated centrifuge, Germany, 40,000 g, 1 h, 4 °C), the whole process being repeated thrice to ensure complete removal. The two process variables, total lectin ratio to zeta potential and incubation time required for coating were optimized by measuring the change in zeta potential of the dispersion. For optimization of zeta potential: lectin ratio and zeta potential: incubation time for the effective coating, negatively charged PCL-NPs were incubated with varying amounts of lectin, i.e. w/w ratios based on polymer weight (0:10, 1:15, 1:20 (w/w) ratio) for a fixed time period of 6 hr and zeta potential was measured (Delsa Nano C, Beckman Coulter, USA). The optimum ratio was determined at which no significant change in zeta potential was recorded on further increasing the lectin. Similarly for the optimization of incubation time, the formulations were incubated with optimum lectin content for different time periods (0, 1, 2, 3, 4, 5, 6, 7 h) and change in zeta potential was measured (18).

In-vitro characterization

Developed PCL-NPs were characterised before and after surface ligand anchoring. The size distribution of PCL-NPs was determined in bi-distilled water by photon correlation spectroscopy (PCS) using a particle size analyser (Brookhaven Instruments Corps). For the determination, 1 mL of NPs was

dispersed in 5 mL of distilled water and sonicated for about 1 hr. The analyses were performed at a scattering angle of 90 °C and a temperature of 25 °C. Formulations were evaluated for their shape and morphology by transmission electron microscopy (TEM) (Hitachi 7500, Japan). Phosphotungstic acid (1%) was used as a negative stain. Carbon coated samples were placed over a copper grid and subjected to TEM analysis. In vitro drug release was performed using dialysis membrane diffusion technique. Briefly, 1 mL of encapsulated formulation was suspended in 1 mL of phosphate buffer solution (PBS, pH 7.4) in a dialysis bag and dialyzed against 250 mL PBS with 0.5% Tween 80 contained in dissolution apparatus (DISSO 2000, Labindia, India), thermostated at 37 ± 1 °C with moderate shaking at 100 rpm. At specific time intervals, a definite volume (1 mL) of the release medium was withdrawn and replenished with fresh PBS and analyzed for AmB and DOX amount using validated HPLC method each for both drugs (AmB and DOX). Each measurement was performed in triplicate and reported as their average (5).

In order to quantify the drug entrapment efficiency encapsulated amount, AmB and DOX was extracted from the PCL-NPs using dimethyl sulfoxide, diluted with methanol and analyzed using HPLC. The HPLC (LC-10ATvp, Shimadzu, Tokyo, Japan) was equipped with a Lichrosphere reverse-phase C18 column (250 × 4 mm, 5 μm; Merck, Darmstadt, Germany). Acetonitrile with KH_2PO_4 buffer (pH 3.5, adjusted with orthophosphoric acid), (60:40, v/v) was employed as mobile phase at 1.0 ml/min flow rate and column effluent was detected with a UV detector at 405 and 235 nm. Results are expressed as AmB and DOX actual loading (drug amount encapsulated per 100 mg of PCL-NPs) and encapsulation efficiency (EE) (ratio between drug amount entrapped in the PCL-NPs and that added during PCL-NPs preparation) ± SD of values collected from three different batches (10).

Ex-vivo stability

The Ex-vivo studies were performed by observing drug leaching and change in particle size following incubation of PCL-NPs with freshly pooled rat serum at 37 ± 1 °C. The drug content of the PCL-NPs was determined by the method described previously with slight modifications (16). PCL-NPs formulations (1 mL) were incubated with 2 ml serum at 37 ± 1 °C for 1, 2, 4, 6 and 24 hrs. After specified time intervals, suspensions were centrifuged at 20,000 rpm for 15 min and supernatant was filtered through 0.22 μm membrane filter. The filtrate was analyzed for drug content by reverse phase high performance liquid chromatography (HPLC) method as described previously (10). The particle size of PCL-NPs formulations was determined after 24 hrs incubation of the

formulations with the serum using particle size analyzer (CILAS, 1064, Marcoussis, France) (5).

In vitro phagocytic uptake studies in macrophage cell line

Adherent mouse macrophage cell line J774A.1 was used for *in vitro* activity against intracellular amastigotes in macrophages, maintained in Dulbecco's modified Eagle's medium (Sigma, USA) supplemented with 10% heat-inactivated foetal bovine serum, 100 U/mL penicillin and 100 mg/mL streptomycin at 37 °C in 5% CO₂ in humidified atmosphere (2). Macrophages (1 × 10⁵ cells/well) in 16-well chamber slides (Nunc, Naperville, IL, USA) were infected with promastigotes (*L. donovani*, Dd8) at multiplicity of infection of 10:1 (parasites: macrophage) and incubated at 37.8 °C in 5% CO₂ for 12 hrs after which chamber slides were washed thrice with PBS (pH 7.2) to remove non-phagocytosed promastigotes and finally supplemented with medium. Different concentrations (0.03, 0.08, 0.13 and 0.2 mg/ml) of 100 mL of free PCL-NPs, PCL-NPs (AmB and DOX), lectin-PCL-NPs in RPMI-1640 medium were added to wells in triplicate. The untreated infected macrophages were used as control. Formulations were then removed by washing after 3 hrs and macrophages were placed in medium for an additional 20 hrs and then examined for intracellular amastigotes under oil immersion objective of light microscope after methanol fixing and Giemsa staining of the slides. At least 100 macrophage nuclei were counted per well for calculating the percentage infected macrophages and number of amastigotes per 100 macrophages. After washing cells were fixed in 10% w/v formalin in PBS (100 mL formalin (37-40% stock solution), 900 mL Water, 4 g/L NaH₂PO₄ (monobasic), 6.5 g/L Na₂HPO₄ (dibasic/anhydrous) and observed by CLSM (Olympus IX 81, Center Valley, PA USA).

Percent parasite inhibition in treated wells was calculated using the following formula reported and published by our associated group previously (10).

$$PI = 100 - T \times 100 / C$$

Where PI is the percentage inhibition, T the number of parasites in treated samples/100 macrophage nuclei and C the number of parasites in control samples/100 macrophage nuclei.

Statistical analysis

Results were expressed as mean ± S.D. Three sets of experiments were performed. The data were statistically processed by one-way analysis of variance (GraphPad; Prism software program) followed by post-hoc Tukey's multiple comparison tests to determine the level of significance.

Differences were considered statistically significant at P < 0.05.

Results

Preparation and In-vitro characterization

PCL-NPs formulations, containing combination of dual agents via double emulsion method were prepared. PCL-NPs were optimized for various parameters. These include drug content, sonication time and polymer content. As the concentration of drugs (AmB and DOX) was gradually lowered, particle size was decreased while percent drug entrapment was increased (Table 1). However, as the concentration of AmB and DOX was gradually lowered, the number of nanoparticles increased (Table 1). It may be attributed to the leaky membrane formations which may result in lower entrapped volume and hence lower size of the particles. This hypothesis however, needs confirmation from experimental studies (10). When concentration of AmB and DOX was used at 5 and 10 mg respectively, PCL-NPs formulations were formed within range, average particle size measured was 236.7 ± 0.04 nm and entrapment efficiency was recorded to be 82.1 ± 1.39 (AmB) and 75.20 ± 0.14 (DOX) for PCL-NPs and again only nanoparticles were observed. Formulation having AmB and DOX of 5 mg and 10 mg respectively (formulation PCL-NP4)

Table 1 Optimization of AmB and DOX (mg) /weight of PCL-NPs (mg)

Formulation code	AmB content (mg)	DOX content (mg)	% Entrapment efficiency	
			(AmB)	(DOX)
PCL-NP1	10	20	65.3±1.10	62.8±0.12
PCL-NP2	8	15	70.1±1.08	68.11±0.16
PCL-NP3	6	12	78.4±1.12	70.18±0.11

Total polymer used-50 mg, sonication time-15 min
*(mean ± S.D) n=3

was considered to be optimum because for intravenous or intracardiac administration purpose, particle size should be below 1µm to prevent formation of emboli in the blood vessels (11) and formulation PCL-NP4 is having particle size in this range. Formulations with optimum drug to polymer content were subjected to sonication for different time periods to optimize the sonication time. Fig 1 shows that as the sonication time was increased from 0 to 15 min, average particle size was recorded to be decreased. Above 15 min (i.e. at 20 and 25 min sonication) particle size were recorded to be increased which may be attributed to the particle coalescence

occurred as a result of the high kinetic energy of the particles and they might have localized in hepatocytes apart of macrophages, the target site (12). Formulations with optimum drug content (AmB and DOX) to polymer content and sonication time were subjected to polymer ratio. From this hypothesis, optimum sonication time was recorded to be 15 min, which gave particle size of 236.7 ± 0.04 nm. As the PCL content was increased from 50 to 200 mg, percent drug entrapment was also recorded to be increased (Fig. 2).

Figure 2 Optimization of PCL content in terms of % drug entrapment and % haemolysis. Total AmB-5 mg, DOX-10 mg, sonication time-15 min, speed-10,000, Temp-25 °C

This may be attributed to the formation of thick layers upon which drugs were encapsulated (13). Also as the PCL content was increased, percent haemolysis was also recorded to be higher (Fig. 2). The mechanism responsible for this toxicity is not understood (14). However, it may be attributed to the subsequent decreased stability of the NPs with the increase in PCL content and initial fast release of drug from these unstable particles (15). Optimum PCL content was found to be 50 mg (Fig. 2) which could entrap maximum amount of drug 82.1 ± 1.39 (AmB) and 75.20 ± 0.14 (DOX) for PCL-NPs with an acceptable level of toxicity towards erythrocytes.

After optimizing the process parameters, PCL-NPs were coated with macrophage specific ligand lectin (18, 19). Moreover, lectin possessed a positive charge, while PCL-NPs were negatively charged which further facilitated the adsorption process and resulted in a reduction of the zeta potential of the dispersion, which was used to optimize the process variables (16, 17). This determinant variable was critically utilized in determining optimal ligand density through optimization of process variables (polymer-to-lectin ratio and incubation time) (18). The increase in average particle size in case of lectin coated PCL-NPs (252.3 ± 0.04 nm) as compared to plain PCL-NPs (236.7 ± 0.04 nm) is an indication of coating. Zetapotential value declined steeply from their initial values, which might have been attributed to the charge quenching of the surface associated with lectin. With a longer incubation time (beyond 6 hr), the amount of residual free lectin was decreased and the change in zeta potential was not significant. This indicated that at the end of

6th hr, the interaction and inter-digitation of added lectin could have completed. The shape and morphology of the PCL-NPs were determined by TEM. The TEM photograph suggested that the PCL-NPs are spherical in shape and multilamellar in nature (Figure 6). The presence of coating on the PCL-NPs surface could also be appreciated from the TEM, which indicates surface intervening and anchoring of ligand (Figure 6). For PCL-NPs the initial negative value of the zeta potential was changed from -12.5 to 4.51 mV on addition of cationic ligand lectin and approached towards a minimum value (Fig. 3).

Figure 3 Optimization of lectin to polymer ratio for complete lectin coating over PCL-NPs. Incubation time of 6 hrs was kept constant.

It was apparently related to the extent of the masking of the surface charge by the lectin. On further addition of lectin especially beyond this optimum ratio (3:1 w/w) no significant change in the zeta potential was occurred for PCL-NPs. Hence optimum ratio of lectin: polymer was recorded to be 3:1 (w/w) for PCL-NPs. This indicated that at an optimal 3:1 w/w ratio of lectin: polymer, the integration of lectin with the surfactant membrane was occurred at saturation level. For optimization of incubation time, the PCL-NPs formulations using the optimum lectin: polymer ratio were incubated with lectin for different time periods (0, 1, 2, 3, 4, 5 and 6h) and the change in zeta potential was recorded (Fig. 4). Table 2 shows the average particle size and percent drug entrapment of optimized formulation of

Figure 4 Optimization of incubation time for complete lectin coating over PCL-Nanoparticles. Lectin to polymer ratio 3:1 w/w was kept constant.

Table 2 Characterization of optimized free and lectin coated PCL-NPs

Formulation code	Nature of ligand	Charge	% Drug entrapment		Average particle size (nm)
			AmB	DOX	
PCL-NPs	----	Negative	82.1±1.39	80.1±1.29	236.7±0.04
Lectin-PCL-NPs	lectin	Positive	75.20±0.14	73.07±0.75	252.3±0.04

*(Mean ± S.D) n=3

PCL-NPs and lectin-PCL-NPs. The increase in average particle size in case of lectin-PCL-NPs as compared to PCL-NPs is an indication of coating, which can be distinguished by dark black boundary of the formulation lectin-PCL-NPs. Also the change in zeta potential of the PCL-NPs indicates the presence of coating as previously zeta potential was negative and after coating it changes into positive. Percent drug entrapment of optimized PCL-NPs and lectin-PCL-NPs formulation was recorded to be 82.1 ± 1.39 (AmB) and 75.20 ± 0.14 (DOX) and 80.1 ± 1.29 (AmB) and 73.07 ± 0.75 % (DOX) (w/w) respectively, revealing that lectin anchoring result in significant increase of the percent drug entrapment (Table 2). Preformed PCL-NPs were used for anchoring of ligand and this may presumably be the reason for the insignificant change recorded in the percent drug entrapment value (17). Relatively high entrapment of AmB and DOX in the PCL-NPs could be attributed to the hydrophobic nature of the drug, since the entrapment was dependent upon lipid: aqueous phase ratio.

Ex-vivo stability

Stability of developed PCL-NPs in serum was measured as percent drug leaching from PCL-NPs and changes in particle size of PCL-NPs after incubation with serum at 37 ± 1 °C. The PCL-NPs were found to be almost constant upon incubation with freshly pooled rat serum (Figure 5). Only 6.6 ± 0.35 and 5.1 ± 0.21 % drug was leached into serum after 24 hr of incubation from plain and lectin coated PCL-NPs, respectively. This may be attributed to the hydrophobic nature of the formulation hence prevented the drug leaching in serum. Results also indicate that lectin coating considerably reduced the leaching of the drug from PCL-NPs (12). Similarly, particle size analysis of PCL-NPs did not show any significant change in the particle size of plain and lectin coated PCL-NPs

after 24 h incubation with serum (data not shown). There was only minor increase in the particle size of plain and lectin coated PCL-NPs.

**Figure 5** In-vitro drug leaching from plain and lectin coated PCL-NPs in serum after different time intervals

In vitro phagocytic uptake studies in macrophage cell line

Qualitative analysis of in-vitro phagocytic uptake of PCL-NPs was studied using macrophage J774.1 cells in light microscopy (Figure 6). AmB and DOX loaded PCL-NPs were non-

**Figure 6** TEM image of lectin coated PCL-NPs (X 40000)

specifically taken up by macrophage cell lines and the maximum uptake was observed at 60 min. Although some PCL-NPs were found distributed and attached to cell surface, active non-specific phagocytic uptake was noticed in most wells on close observation. Staining was carried out using Giemsa stain elsewhere in the body and its bioavailability towards spleen was nominal. Free nanoparticles alone caused in very low or negligible suppression due to its immune response. Ultimately, it was clearly clarified that an optimal quantity of AmB and DOX required is reaching spleen and liver via macrophage transport. A 74.2 ± 1.9 (AmB) and 70.52 ± 1.2 (DOX) parasitic suppression indicates that our prepared delivery system can be a capable tool for anti-leishmanial therapy.

Discussion

PCL-NPs have been recognized as potent drug delivery systems for the treatment of Visceral leishmaniasis (VL) because both nanoparticles as well as leishmania parasite are taken up by the same reticuloendothelial system (RES) and it creates an ideal situation for a high degree of drug parasite interaction (16). Furthermore, if suitable ligands are incorporated to PCL-NPs so that they could easily be recognized by the macrophages (host for the parasite) receptors, then these customized PCL-NPs could probably be used successfully as carriers for site specific delivery (17). The majority of the drugs used formerly in the therapy of visceral leishmaniasis were toxic. However when those drugs were Nanoparticles-encapsulated, they were found to be less toxic and more efficient in the therapy of visceral leishmaniasis (16). In the present study the efficacy of AmB and DOX in the form of novel carrier, PCL-NPs was tested against VL in macrophage cell line and compared with free AmB and DOX and indicates that prepared delivery system can be a capable tool for anti-leishmanial therapy. This may be attributed to the nano size range of PCL-NPs which forced the particles to accumulate in the macrophage rich organs like spleen, hence related to a different drug biodistribution in the form of carrier. Moreover formulation Lectin-PCL-NPs was found to be most potent as compared to PCL-NPs which includes involvement of mannose receptors expressed onto the membrane of macrophages of the liver and spleen. These receptors might have been involved in the selective and higher uptake of the ligand appended nanoparticles (lectin-PCL-NPs) due to ligand-receptor interaction (16).

Conclusion

We have proved the efficacy of AmB and DOX-loaded PCL-Nanoparticle (PCL-NPs) delivery system used for anti-VL using macrophage-targeted drug delivery approach. The nanoparticles of PCL were successfully prepared by double emulsion method with optimum size and entrapment. By exploiting passive targeting modes, total dose required for therapy was grossly cut down to few orders extent less than free drug, rendering the therapy favourable and affordable. The developed systems (plain and lectin coated PCL-NPs) via intravenous/ intracardiac administration appear promising for the treatment of VL specifically and hepato-splenic candidiasis. Developed formulation system exhibited no major side effects and thereby ensuring safer use over time and is possibly a better substitution for antimonials or other anti VL drugs which is suffering resistance and toxicity concerns. Further extensive studies on stability aspects should be carried out before proceeding to industrial scale-up.
